CHAPTER 5-6
ECOPHYSIOLOGY OF DEVELOPMENT: FRAGMENTS

Figure 1. *Dicranum viride*, a moss that fragments regularly by a row of abscission cells across the upper half of the leaf. Note the broken leaf tips. Photo by Michael Lüth.

Fragmentation

Fragmentation may be random pieces that break due to abrasion, decay, or animal severance, or they may be programmed genetically by means of an abscission layer such as demonstrated in *Dicranum viride* (Figure 1). In certain habitats, fragmentation may be a regular phenomenon, accounting for nearly all the reproduction.

Even fossil evidence supports the importance of fragments in the dispersal and reproduction of bryophytes (Miller 1985). And buried fragments often retain viability, providing the source for the flora when a disturbance returns an area to previous conditions (Wasley 2004).

Yet, when we diagram life cycles, fragmentation is usually ignored, and certainly for many flowering plants it is unimportant. However, in bryophytes it is often the fragments that perpetuate the species. Likewise, Giordana and coworkers (1996) found that regeneration from the detached leaves was the major form of regeneration in moss *Pleurochaete squarrosa* (Figure 2). Other bryophytes, such as *Hyophila crenulata*, share their successful regeneration from fragmentation with other means such as gemmae (Olarinmoye 1981).

Mishler and Newton (1988) contend that in perennial mosses reproduction and spreading is almost entirely by means other than spores. Many populations exist for which capsules are unknown, particularly for dioicous taxa (having males and females on separate plants; unisexual). Even when all individuals in the population can produce both sexes (monoicous; bisexual), water is needed at the right time for sperm and egg to meet, so success rate will vary with habitat and with weather in a given year. Newton and Mishler (1994) suggest that vegetative reproduction, including specialized propagules, can occur...
under more stressful conditions. Whereas spores germinate best on previously uncolonized substrates, vegetative reproductive units can do well even in contact with existing colonies. However, they suggest that such vegetative units cannot travel as far as spores – tradeoffs again.

The success of fragments within short range (Newton & Mishler 1994) is supported by experiments by Nehira and Nakagoshi (1987). They removed a community of bryophytes and found that the community became re-established within 1-2 years. Most of the growth occurred in spring and autumn despite little seasonal variation in propagule dispersal. Thalloid liverworts and pleurocarpous mosses were able to regenerate more quickly than the acrocarpous mosses. Yet these same fragments may have been eaten or decayed before ever growing if the researchers had not removed the parent colony. Newton and Mishler (1994) found that at least for the dry habitat mosses they studied, the parent plants seemed to inhibit growth of the fragments, with growth commencing once they were separated.

Fragmentation is likely to determine success of the species in some environments. Miles and Longton (1990) found that Funaria hygrometrica (Figure 5) reproduced and spread easily by spores, whereas Atrichum undulatum (Figure 6) and Bryum argenteum (Figure 7) were likely to experience failure before sporelings produced gametophores. On the other hand, these latter two species freely accomplished regeneration from shoot fragments. This ability of Atrichum to regenerate easily from leaf fragments permitted it to dominate the ground cover rapidly after the construction of a parking lot on the Michigan Technological University campus (Glime 1982). Funaria hygrometrica, on the other hand, apparently manages to arrive, presumably by spores, and colonize charred ground within a year after a fire, as occurred after the big Yellowstone fire (Glime pers. obs.).
Arctic and Alpine

In the Arctic, fragments on the ice are common, and are easily moved around over the smooth surface, permitting rapid transport over considerable distances. Miller and Howe Ambrose (1976) found more than 4000 viable moss fragments per cubic meter of snow on a summer snowbed on Bathurst Island in the Canadian high Arctic. These regenerated by protonemata, shoots, or rhizoids, or simply resuming growth. Liverworts, however, did not fare as well, with only one fragment producing new growth. They surmised that such moss fragments may be "routine" in Arctic climates.

Mogensen (1986) found that *Platydictya* (Figure 10) was dispersed in Greenland primarily by vegetative propagules and Bonde (1959) found viable *Polytrichum piliferum* (Figure 11) fragments among the wind-blown debris of a Colorado glacier. Lindskog and Eriksen (1995) found that the fragments of mosses, in particular, that were on the glacier reflected accurately the composition of the surrounding vegetation.

The importance of fragments may reach its climax in the Antarctic. In colonizing a new Antarctic volcanic island, fragments of *Campylopus* (Figure 12), *Marchantia*, (Figure 13) and *Bryum* (Figure 7) species seemed to be the most important means of arrival (Smith 1984).

Streams and Other Aquatic Habitats

In flowing streams, sporophytes seem rare, and asexual propagules seem to be unimportant. However, significant dispersal can occur from fragments during spring runoff, and entire clumps as well as branches and smaller fragments become impinged on rocks and roots in the stream. The larger surface area of fragments makes it more likely that they will become lodged than will the small spores and asexual propagules. Glime *et al.* (1979) demonstrated that for *Fontinalis duriaei* these actually do become established in nature, occasionally even achieving upstream movement (by feet of bears?).

For aquatic mosses and liverworts, fragmentation may be the only means of reproduction for many years before appropriate conditions exist for completing sexual reproduction. In dioecious mosses such as *Fontinalis*, sexual reproduction seems to be so infrequent as to be totally ineffective as a means of providing dispersal units (spores), whereas fragments are numerous during times of ice melt and high water (Figure 14; Conboy & Glime 1971, Glime *et al.* 1979, Glime & Knoop 1986). Even when spores are produced in this genus, the spore faces numerous challenges in becoming located where its subsequent protonema will neither be washed away nor desiccated, and sufficient light will be available for development. Since there is no documentation of the occurrence of any protonema of any *Fontinalis* species in the field, we can only conjecture about the success of reproduction by spores in this genus.

Dedifferentiation

*Dedifferentiation* is the process involved in the return of a cell to its embryonic state. It is necessary before a mature cell can form into a different kind of cell, or into a protonema, permitting the development of new plants from fragments. In bryophytes, virtually all cells seem to have the ability to undergo dedifferentiation once they have been isolated from the intact plant (Giles 1971). This is not the case for cells such as xylem elements of tracheophytes, which no longer have protoplasm and hence are non-living.
Moss fragments seem to retain their polarity, resulting in protonemata at the apical end and rhizoids at the basal end, but inverting them causes the base to act as the apex and vice versa (Westerdijk 1907), suggesting a gravimetric response by some growth factor. Mosses tend to have more regenerative ability at the base of the gametophyte than at the apex. Their sporophytes, however, are strongly polar in regeneration (von Wettstein 1924). Liverworts, on the other hand, seem to be much more strongly polar, and new growth is nearly restricted to the apical end of the gametophytes, but the sporophyte seems to lack polarity (Giles 1971). This strong polarity of the liverwort gametophyte regeneration, however, decreases with tissue age (Kreh 1909).

Earliest known reports on regeneration from bryophyte fragments come from Necker in 1774 (Giles 1971). Kreh (1909) showed that for liverworts, every part of the plant except the antheridia could regenerate. Nevertheless, few reports of liverwort regeneration from fragments are known. In mosses, even the seta will regenerate into a protonema, forming diploid gametophytes (von Wettstein 1924).

It is common for the nuclei to increase in size in dedifferentiating cells (Giles 1971). The dedifferentiation process involves a sort of "budding" of the chloroplasts and mitochondria, producing more of these organelles. At the same time, nucleolar volume increases only in regenerating cells. We now understand that the nucleolus is not an organelle in its own right, but rather that it is the site of extensive protein synthesis, hence staining more densely. This is an indication of building activity in the regenerating cell.

In *Campylopus pyriformis* (Figure 15) fragments, it is the chloronema that gives rise to buds, with no caulonema forming. By contrast, and unlike the growth from a spore, the caulonema of *Plagiomnium affine* (Figure 16) grows nearest the plant fragment and the chloronema is the farthest and youngest tissue (Sironval 1947; Bopp 1959a,b; Giles 1971). The ensuing buds develop, therefore, nearest the leaf fragment from the caulonema. Up to 100 secondary protonemata may originate from the dedifferentiated leaf cells of a single leaf in this species.

### Callose Formation

Scherp et al. (2001) documented the formation of callose in tissue fragments in all groups of multicellular photosynthetic organisms, including bryophytes. They found that in bryophytes and other multicellular green plants, callose is a regular component of the developing septa in juvenile cells during cytokinesis. Wound callose did not occur in cells that already had callose in the newly formed septa.

### Establishment

It appears that fragments may survive better in water than spores, thus providing an additional means of long-distance dispersal. Dalen and Söderström (1999) tested five species of mostly terrestrial mosses and found that in all five taxa, regeneration frequency of fragments was lower than that of spores, but that fragments survived as well in water as they did dry, whereas spores did not. Light quality and intensity may be influential in success of fragments. Dagar and coworkers (1980) found that for the thallose liverwort *Riccia discolor* regeneration is best in diffused light. Red light can induce regeneration; far-red inhibits it (Giles & von Maltzahn 1967, 1968). There is evidence the red/far-red system may affect the "budding" or division of the chloroplasts (Hahn & Miller 1966), and its reversibility suggests that phytochrome may be active during the process. Little else seems to be known about light effects specifically on fragments, so these phenomena may be restricted to certain taxa or habitats.

When dispersal occurs over long distances, it is quite likely that only one gender will arrive, making its survival dependent on asexual means. As discussed elsewhere, fragments seem to provide the easiest means by which bryophytes can be propagated for gardens, so one should expect that nature makes widespread use of this ability as well. When a plant is damaged, the damaged surface will often produce protonemata and/or rhizoids (LaRue 1942) and subsequently develop a new leafy gametophore. In other cases, the new plant may develop directly with no protonemal intermediary, as in the leafy liverwort *Scapania undulata* (Figure 17) that developed from a leaf fragment (Figure 18; Glime 1970).
Mishler and Newton (1988) demonstrated that fragments can require conditions opposite to those required for spores. In their study, *Syntrichia princeps* (Figure 20) fragments were slightly more successful when they experienced periodic drying, whereas the spores required continuously hydrated conditions. With such requirements, it is easy to understand why fragments are more successful on rocks and sand than are spores. Mishler and Newton attribute this success to the ability of fragments to produce a protonemal mat and new shoots much more rapidly than could spores. Furthermore, as mentioned earlier, the existing plants exhibited a much stronger inhibitory effect on the spores than on the fragments.

On the other hand, both spores and fragments can be inhibited by the presence of mature plants (Mishler & Newton 1988). *Dicranum* (Figure 1, Figure 3) seemed to be more inhibitory than *Syntrichia princeps* (Figure 20), perhaps relating to the dry habitat of the latter. They considered that at least some of this inhibition was due to chemical exudates.

In an aquatic habitat, Florschütz and coworkers (1972) found that fragments of *Fissidens crassipes* (Figure 21) produced caulonemata, this time on moist bricks. This ability permitted them to spread rapidly in response to a rise in water temperature.

Regeneration often occurs from small leaf fragments that have begun to decay. This could be an indication that an inhibitor has been lost, or some colonizing...
microorganism could be providing a hormonal signal that starts the development. When growing *Leucolejeunea clypeata* on Ca-free media, Geldreich (1948) discovered that only contaminated leaves of Ca-deficient plants produced regenerants. It was only mature or old and necrotic leaves that regenerated, and these Ca-deficient leaves had oil bodies that were characteristic of old, senescent leaves. Since the contaminating microorganisms were typical of soil flora, and regenerants of this species are known in nature (Fulford 1947), perhaps the microorganisms do indeed play a role in providing the necessary stimulus.

Liverworts rarely regenerate from fragments. Occasionally a leaf may produce a new plant, as for example that of *Scapania undulata* (Figure 17-Figure 18), an aquatic leafy liverwort mentioned earlier (Glime 1970). Could it be that liverworts dry out too rapidly and cells lose their viability before new plants can arise? Would this explain the accomplishment of this aquatic species?

**Growth Regulators**

Like all other developmental processes, hormones and other growth regulators influence the developmental pathway of fragments. Patidar and coworkers (1987) found that 0.03 ppm gibberellin can stimulate regeneration in the thalloid liverwort *Targionia hypophylla* (Figure 22). Concentration is of course important; at 0.1 ppm gibberellin is inhibitory to *T. hypophylla*.

Few studies seem to have centered specifically on growth regulators of fragments, yet many in vitro studies are actually studies of fragments, particularly those of pleurocarpous mosses. Presumably, the same growth regulation applies to fragments as to the intact plants covered earlier. Yet, literature on the wound response seems to be lacking, as is literature on the remarkable ability of some fragments to persist under extremely stressful conditions. For example, we have grown *Fontinalis flaccida* from specimens dried for three months under herbarium conditions (ca. 30% relative humidity). In another case, *Fontinalis novae-angliae* that had been boiled for about 12 hours daily for two weeks developed new leaves on one portion of the remaining stem when it was returned to its native stream (Glime & Carr 1974). And what permits a partially decayed stem to suddenly spring forth a new plant after it has been uncovered from many years of burial (During *et al.* 1987)?

**Animal Dispersal**

Dispersal by animals is scarcely known in the bryophytes. Yet, we must suppose that the various activities of animals contribute to bryophyte movement. Various aquatic insects, especially Trichoptera (caddis flies), use mosses or liverworts in their cases, so the insect will carry the bits around wherever it goes. When drift carries the insect downstream, the moss goes too, and if the insect crawls upstream in the quiet interface at the bottom, the moss comes along. Lacewings [*Leucochrysa* (*Nodita*) *pavida*] carry viable bryophytes (and lichens) on their backs as camouflage (Slocum & Lawrey 1976).

Bears, beaver, and other animals can get mosses tangled among their toes and carry them for miles. Birds carry them off to build nests. I have even concluded that the turtle in my garden room was responsible for the distribution of *Conocephalum conicum* (Figure 23) all over the room from the single spot where it had been planted. When the turtle died, the spread of the liverwort stopped. In a field experiment, I found fragments of tagged *Fontinalis duriae* (Figure 24-Figure 25) upstream from their initial location, a movement that could only have been effected by animals such as bears or humans.
It is likely that rodents contribute to dispersal, although they may do more harm than good. I have watched chipmunks run across my moss garden and kick up clumps as they ran. Nancy Ironsides (Bryonet 10 June 2011) found rhizoids on the apical leaves of *Leucobryum glaucum* (Figure 26) and attributed these to disturbance by animals. Pénzes Kónya (2003) considered "big wild animals" to be major dispersers of *Leucobryum juniperideum* (Figure 27) during dry periods. The caducous leaves function as gemmae by producing rhizoids (Figure 28) and forming new plants, especially during the rainy spring, but the disturbance of dry mosses seems to outpace the regeneration from disturbed plants.

Others may spread bryophytes as they eat them (Slack 1936, Mutch & Pritchard 1984), particularly if they only digest the surface organisms and return the moss fragments with their feces. Suren and Winterbourn (1991) found that 14 aquatic invertebrate taxa had bryophyte fragments in their guts, and two tipulid larvae regularly consumed bryophytes. I tested the hypothesis that rainbow trout, known to strike at anything, could serve as dispersal agents by eating the aquatic *Fontinalis duriaei* (Figure 24–Figure 25). However, the fish could not be tempted to strike at or eat the moss, even when it housed numerous aquatic insects. Finally, we force fed the fish. The moss was delivered back as feces in a neat, cylindrical package with bright green moss (Figure 29). At last it seemed we had demonstrated a potential upstream dispersal mechanism! But, alas, we were surprised the following day to find that the moss had lost all its color, even though it was maintained in a gallon jar of its own stream water at a cool temperature. It does not appear that rainbow trout are likely dispersal vectors after all!

I have watched larvae of the Rhyphidae dipteran eat wet, dirty (most likely with diatoms) mosses and observed fragments of green moss come out the other end, clean. These fragments would be ideal propagules, although not dispersed very far, but I did not culture them to see if they met the same fate as the trout package.

Further discussion of bryophyte fragment dispersal is in the adaptations subchapter on dispersal.
Summary

Fragmentation results from random breakage or from genetically programmed cleavage areas on leaves, buds, or stems. For perennial mosses, especially pleurocarpous mosses, it is typically the primary means of spreading. Arctic/alpine and aquatic habitats may rely primarily on this type of reproduction. Fragments are more likely to become established than spores and survive better in water than do spores. Their establishment can be inhibited by the presence of mature plants, but they have a greater competitive ability than spores.

Regeneration from mature cells requires dedifferentiation and may begin as protonemata, rhizoids, or both. Light quality and intensity may play a role in early development. Little is known about growth regulation, but gibberellin can stimulate regeneration at least in some bryophytes. Dispersal can be accomplished by wind, water, and animals, sometimes because the animal transports the bryophyte for use in a nest or house.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll and KT with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen.
