CHAPTER 11-10
AQUATIC INSECTS: HOLOMETABOLA – COLEOPTERA, SUBORDER POLYPHAGA

Suborder Polyphaga

This suborder includes more than 90% of the Coleoptera species. As its name suggests, it eats a tremendous variety of foods.

Helophoridae

This is a family of North America and Europe and has only one genus, Helophorus (Helophoridae 2014). They are relatively small (2-9 mm) (Helophoridae 2014) and live primarily in wetlands (Helophoridae 2015). Most adults live in shallow standing water where they are saprophagous (Fikáček 2009) (organism that feeds on decaying organic matter). Larvae, on the other hand, live in terrestrial, but moist, habitats near water and are predators on small invertebrates.

Helophorus grandis (Figure 2) occurs among the aquatic mosses in a stream in Yorkshire, UK (Gilbert et al. 2005). In Canada, Helophorus orientalis (Figure 3) occurs in wet mosses beside small streams (Majka 2008). Helophorus strigifrons (Figure 4) lives in bogs in North Hampshire, UK, among moss and litter (Denton 2013).

Figure 4. *Helophorus strigifrons* adult, a bog dweller in North Hampshire, UK, among moss and litter. Photo by Zoologische Staatssammlung Muenchen through Creative Commons.

**Hydrochidae**

Although this family is worldwide, it has only one genus, and most of the records are from Europe (Hydrochidae 2015a). Adults and larvae live in both quiet and flowing water where they are herbivores—shredders (Hydrochidae 2015b). The adults range 4-60 mm long. Some of these are associated with bryophytes.

*Hydrochus ignicollis* (Figure 5), a very rare species in Ireland, appeared in collections only twice between 1988 and 1996 (Nelson 1996). Both finds were from mossy calcareous fens adjacent to marl lakes. These are alkaline lakes with unconsolidated calcium carbonate or lime-rich mud or mudstone which contains variable amounts of clays and silt (Figure 6-Figure 7).

Figure 6. Marl lake in Jasper National Park, Canada. Photo by Janice Glime.

Figure 7. Marl at margin of marl lake in Jasper National Park, Canada. Photo by Janice Glime.

**Hydrophilidae – Water Scavenger Beetles**

This is a worldwide, mostly aquatic family, typically in open water (Cotinus 2005). The larvae often emerge from the water to pupate, usually hanging from moss at the edge of the water (Water Beetles 2014). The final larval skin is found beneath the pupa. The adults (1-40 mm) are mostly scavengers, but some are predators; larvae are often predators (Cotinus 2005).
Some Hydrophilidae join the Dytiscidae as common beetles swimming in bog waters. *Enochrus* (Figure 8-Figure 9) is a common genus there (Denton 2013). *Enochrus affinis* (Figure 10) is often abundant in Sphagnum-dominated (Figure 46) areas of acidic heathland pools (Figure 11) of North Hampshire, UK. *Enochrus coarctatus* (Figure 12) is a mire dweller, preferring older detritus pools but also living in Sphagnum-filled large bog pools. *Enochrus ochropterus* (Figure 13) does not occur in areas of pure Sphagnum where the *Enochrus* is exclusively *E. affinis*. However, it does occur in richer areas with *E. coarctatus*. The importance of the Sphagnum in its habitats may be due to its role in acidification. *Enochrus fuscipennis* (Figure 14) lives in the Sphagnum-choked shallow pools of undisturbed blanket bogs in Dartmoor, UK (Boyce 2011). *Enochrus hamiltoni* (Figure 15), on the other hand, lives in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008). In the Appalachian Mountain streams, eastern USA, the genus *Enochrus* can occasionally be found among mosses, as well as the genus *Tropisternus* (Figure 16-Figure 17) (Glime 1968).
Chapter 11-10: Aquatic Insects: Holometabola – Coleoptera, Suborder Polyphaga

Figure 17. *Tropisternus natator* adult, an occasional moss inhabitant in Appalachian Mountain, USA, streams. Photo by Donald S. Chandler.

The genus *Laccobius* (Figure 18-Figure 19) associates with mosses in both stream and mire habitats. *Laccobius reflexipennis* (see Figure 18) live in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008). *Laccobius atratus* in Ireland and Great Britain occurs in *Sphagnum* (Figure 46) bogs and other peatlands (Friday 1987; Nelson 1996; Denton 2013). *Laccobius ytenensis* adults live among mosses around the tiny pools that occur in the seepage lines of UK bogs (Denton 2013).

Figure 19. *Laccobius* adult with open wings showing the membranous wings under the hardened elytra. Photo by Michael Schmidt through Creative Commons.
**Chaetarthria siminulum** (Figure 20) can be present in "huge" numbers among mosses at the edges of ponds (Denton 2013). It also lives among mosses in fens and in fen litter.

![Figure 20. Chaetarthria siminulum adult with plastron.](image)

When the plastron is full of air, the beetle must cling to vegetation in order to descend into the water column. Photo by Gerard Visser.

Hebauer (1994) found **Crenitis punctatostriata** (Figure 21) in the high moors, living as a tyrphobiont. **Hydrobius fuscipes** (Figure 22-Figure 23) on Prince Edward Island (Majka 2008) occur in **Sphagnum** (Figure 46) bogs and other peatlands.

![Figure 21. Crenitis punctatostriata adult, a beetle that lives in bogs of the high moors.](image)

![Figure 22. Hydrobius fuscipes adult, a species of Sphagnum bogs.](image)

Figure 22. **Hydrobius fuscipes** adult, a species of **Sphagnum** bogs. Photo by Tim Faasen.

**Berosus luridus** (Figure 24, Figure 25) is tyrphophilic, living among **Sphagnum** (Figure 46), but can also be found in other places (Tim Faasen, pers. comm.). I have found no other records of it living among **Sphagnum**, but it is rare in the Netherlands and may be rare elsewhere. Perhaps the **Sphagnum** provides a relict habitat, a safe site where conditions are still tolerable.

Figure 24. **Berosus luridus** adult on moss, a rare beetle in the Netherlands, but present in bogs among **Sphagnum** there. Note the air bubbles on the moss; these can be used to replenish the air supply. Photo by Tim Faasen.
In tropical Africa, the genus *Anacaena* is probably more common than is recognized. Komarek (2004) described nine new species. Among these, four were from mosses. *Anacaena capensis* occurs among the mosses and leaf litter of mountain rivulets in South Africa. *Anacaena glabriventris* lives among mosses in small streams; *A. reducta* likewise lives among mosses in small streams, but with steep channels. *Anacaena tenella* lives among *hygropetric* mosses (mosses growing on vertical rock faces where a thin film of water flows) in mountain streams. *Anacaena limbata* (Figure 26) lives in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008).

*Anacaena globulus* (Figure 27) lives among *Sphagnum* (Figure 27) in bogs in Europe and can be collected by squeezing the moss (Buczyński et al. 2014). However, Faasen (personal communication) does not find them typically in *Sphagnum* bogs in the Netherlands, but considers them widespread, occasionally occurring in bogs.

Also in Dartmoor, UK, *Helochares punctatus* (Figure 28) is an obligate mire species, living among saturated *Sphagnum*, particularly *S. cuspidatum* (Figure 29), of pools and acid flushes.

Nelson (1996) found several additional species of *Hydrophilidae* in Irish mossy fens. These included *Cercyon convexiusculus* (Figure 30-Figure 31) in mossy fens. In North Hampshire, UK, Denton (2013) found this species to be abundant in detritus and rotting leaf litter, but also among mosses that bordered richly vegetated sites. *Cercyon marinus* similarly occupied mosses or decaying organic matter at the water's edge in Ireland (Nelson 1996).
*Cercyon ustulatus* (Figure 32) occurs in mossy areas of ponds and also occurs among mosses growing on sewage filter beds (Denton 2013).

*Paracymus scutellaris* (Figure 33) occurs among peat mosses in Ireland (Nelson 1996).

Figure 33. *Paracymus scutellaris* adult, a peat moss dweller in Ireland. Photo by Udo Schmidt.

**Hydraenidae – Minute Moss Beetles**

Adults of *Hydraenidae* (Figure 34), known as minute moss beetles (1-3 mm length), are aquatic, but the larvae drown if completely submersed (Watson & Dallwitz 2012). Even adults are poor swimmers (EOL 2014); most eat plants, but a few are carnivorous or saprophagous (feeding on decaying organic matter) (Hydraenidae 2014). They are sparsely distributed worldwide with a concentration in Europe (EOL 2014).

Sarr *et al.* (2013) found that *Hydraena* was correlated with a moss substrate in Northwest Spain. Berthélemy (1966) found this family commonly among mosses in the Pyrénées, including *Hydraena gracilis* (Figure 35), *H. minutissima*, and *H. pygmaea* (Figure 36), with the latter two being considered muscicoles (thriving among mosses). He also considered *Hydraena pulchella* (Figure 37) and *Hadrenya* to be muscicoles. Nelson (1996) reported *Hydraena gracilis* as a common and widespread species in Britain where it lives on mossy rocks in fast-flowing streams and rivers.

Figure 36. *Hydraena pygmaea* adult, a muscicole in the Pyrénées. Photo by Tim Faasen.

Figure 37. *Hydraena pulchella* adult, a tiny beetle that lives among stream mosses in Europe. Image through Creative Commons.

*Hydraena nigrita* is a tiny beetle that lives among mosses at the edges of streams, but it will climb out if the moss is placed under water (Anderson 2014). It is considered vulnerable because of siltation and loss of habitat (Foster et al. 2009). *Hydraena rufipes* (Figure 38) lives among mosses (Nelson 1996; Knight 2014) and fine shingle (mass of small rounded pebbles) along rivers (Nelson 1996).

Figure 38. *Hydraena rufipes* adult, a species that lives among mosses along rivers. Photo from Zoologische Staatssammlung Muenchen through Creative Commons.

Hebauer (1994) found similar species representation from this family in middle Europe. Among the stream mosses he found *Hydraena minutissima, H. pygmaea* (Figure 36), and *H. pulchella* (Figure 37). Several more used mosses or algae as a substrate: *Ochthebius granulatus* (Figure 39), *O. metallescens* (Figure 40), *O. exsulpultus* (Figure 41), *O. melanescens, O. colveranus,* and *O. halbherri*. Eggs of *Ochthebius* are either naked or somewhat covered by loosely applied silk provided by the mother; the eggs hatch in 7-10 days. In rivers in Northwest Spain, Sarr et al. (2013) found that *Ochthebius heydeni* was likewise correlated with a moss substrate.

Figure 39. *Ochthebius granulatus* adult, a stream moss dweller in middle Europe. Photo by Magnus Manske.

Figure 40. *Ochthebius metallescens* adult, a beetle that uses mosses and algae as substrates. Photo by Tim Faasen.
Limnebius nitidus (Figure 42) is among the smallest of the water beetles and in addition to wet mud, it makes mosses in swamps and at the edges of pools and streams its home (Nelson 1996). Adults are a mere mm long, so these scavengers of dead plants and animals are easily overlooked (Hilsenhoff 1975). Eggs of this genus are either naked or somewhat covered with loosely applied silk and hatch in 7-10 days (Usinger 1956). In my studies in the Appalachian Mountain streams of the eastern US, this genus likewise occurred among submerged mosses (Glime 1968).

Hygrotus decoratus (Figure 43) lives in shallow, mossy fens in North Hampshire, UK, where mosses may provide safe sites for larvae and adults (Denton 2013). Hygrotus novemlineatus was reared with Chironomidae larvae as a food source (Nilsson 1983). Mosses were provided in the culture chamber. After a few days, the beetles laid eggs, attaching them to branches of mosses. But is this a normal substrate for egg-laying in nature? The habitat seems suitable, providing lots of Chironomidae larvae as food. This genus should be sought among bryophytes in other fens.

Ptiliidae – Featherwing Beetles

This is a large, worldwide family of minute (0.3-2 mm long) beetles (Ptiliidae 2015). The egg size is half the length of the body and only one is developed at a time, permitting the female to store a large energy supply in the egg. Their wide-ranging habitats include moist leaf litter, under bark of dead trees, along sand and gravel banks of rivers and streams, beneath seaweed on beaches, in mammal nests, on dung, rotting cacti, ant and termite colonies, and other habitats containing rotting or damp organic material. And some seem to live their entire lives in bogs.

The small size of several Ptiliidae beetles – Tychobuthinus bythinoides (Staphylinidae or Ptiliidae; Figure 60), Ptiliopycna moerens (Figure 44), Acrotrichis (Figure 45) – and other small beetles in bogs seems to correlate with a high incidence of parthenogenesis (reproduction from an unfertilized egg) in relict (habitat that survived from an earlier period) bogs (Dybas 1978), most likely having poor dispersal as an additional selection factor.
Figure 45. Acrotrichis sp. adult, a parthenogenetic inhabitant of relict bogs. Photo by Joyce Gross.

Silphidae – Large Carrion Beetles

This family is predominantly in the Northern Hemisphere, although scattered records exist in the Southern Hemisphere (Silphidae 2015a). Ranging in size from 7-45 mm, the family is rare in the tropics where ants might out-compete them (Silphidae 2015b). As the common name implies, the family feeds on decaying organic matter. Because of this feeding behavior, forensic scientists use their stage of development to determine how long a body has been dead.

Despite the need to find new carcasses as their carcass home ages, the Silphidae use walking as their primary means of locomotion (Silphidae 2015b). Most of their activity occurs at night.

The Silphidae have a variety of defenses (Silphidae 2015b). These include color warnings from aposenatism (use of bright colors to advertise danger or unpalatability) to Batesian mimicry (mimicking the coloration or behavior of a species that is poisonous or unpalatable), chemical defenses, and parental care. And many of them use camouflage, having dark colors with a mix of gold, black, and brown to blend with their environment.

Some carrion beetles (Silphidae) occur in bogs. Beninger and Peck (1992) described the resource use by Nicrophorus species (carrion beetles, Silphidae) in a Sphagnum (Figure 46) bog near Ottawa, Canada, and found that resource use differed little from resource use in forested habitats. However, Nicrophorus vespilloides (Figure 47) used only small carrion (Figure 48) in the bog for reproduction, whereas the closely related N. defodiens (Figure 49) went to the nearby forest for reproduction. Likewise, N. sayi (Figure 50), N. orbicollis (Figure 51), and N. tomentosus (Figure 52), also bog inhabitants, were rarely associated with the small carrion of the bog, but rather reproduced mostly in the forest.
Figure 49. *Nicrophorus defodiens* adult, a bog dweller that goes to the forest to reproduce. Photo by Erin.

Figure 53. *Gymnusa brevicollis* adult, a beetle that lives among saturated *Sphagnum* at the edge of bog pools of wet acid mires. Photo from Zoologische Staatssammlung Muenchen through Creative Commons.

**Staphylinidae – Rove Beetles**

These beetles are distinctive in having short wings that cover less than half the abdomen (Bartlett 2004). This large family has about 58,000 species, ranging in size from 1 to 35 mm, but mostly 2-8 mm (Rove Beetle 2014). Distribution is worldwide, but records are lacking in vast areas of Asia and Africa. They live in every imaginable type of habitat and likewise eat everything – except living plants! There is now one exception to that – a recent discovery of a herbivore.

Like the *Carabidae*, the *Staphylinidae* are not aquatic, but likewise inhabit bogs (Boyce 2011). In Dartmoor, UK, *Gymnusa brevicollis* (Figure 53) is stenotopic (able to tolerate only a restricted range of habitats or ecological conditions). Its preferred habitat is saturated *Sphagnum* (Figure 46) in extremely wet acid mires where they can be found at the edge of bog pools.
Mylleena kraatzi (Figure 54), a nationally (UK) rare species, is restricted to very high quality acid mires with abundant bog mosses (Boyce 2011). It is collected by shaking the Sphagnum (Figure 46) and litter, suggesting close ties with these two substrates. Oxypoda procerula (Figure 55) is likewise sampled by shaking the litter and Sphagnum, indicating that it is directly a moss dweller.

Figure 54. Myllaena vulpina adult. Myllaena kraatzi is a rare species of high quality acid mires in the UK. Photo by Reginald Webster, Jan Klimaszewski, Georges Pelletier, and Karine Savard through Creative Commons.

Oxypoda procerula adult, a Sphagnum and litter dweller. Photo by Udo Schmidt through Creative Commons.

Figure 55. Oxypoda procerula adult. Oxypoda procerula and litter dweller. Photo by Udo Schmidt through Creative Commons.

Philonothus nigrita (Figure 56) is a characteristic species in Sphagnum-dominated (Figure 46) acid mires (Boyce 2011). It can be found by treading on the moss cushions, causing it to float out of the saturated Sphagnum. Stenus brevipennis (see Figure 57) lives among Sphagnum in blanket bogs. Stenus kiesenwetteri (Figure 58) is rare in the UK, occurring in very wet Sphagnum (Butler 1886).

Figure 56. Philonothus nigrita adult, a species that characterizes Sphagnum-dominated acid mires. Photo by Marko Mutanen through Creative Commons.

Stenus biguttatus adult. Stenus brevipennis lives among Sphagnum of blanket bogs. Photo through Creative Commons.

Figure 57. Stenus biguttatus adult. Stenus brevipennis lives among Sphagnum of blanket bogs. Photo through Creative Commons.

Unlike the other Staphylinidae discussed here, Dianous coerulescens (Figure 59) lives where water trickles over mosses and liverworts (Butler 1886).

Figure 59. Dianous coerulescens adult on leafy liverwort. Photo by Malcolm Storey through Creative Commons.

The Pselaphinae beetles are represented along the postglacial fringe in the central and eastern United States where they inhabit Sphagnum (Figure 46) bogs (Reichle 1966). More than 20 species of pselaphids characterize these bogs. They are relict species with specific habitat...
requirements and poor dispersal ability. Some have very specific temperature range requirements: *Tychobythinus bythinioides* (=*Bythinopsis tychoides*; Figure 60), 21.5±0.81, 25.9-15.3°C; *Decarthron defectum*, 28.5±0.55, 31.4-24.0; *Pselaphus ulkei*, 19.5±0.86, 24.7-13.0; *Reichenbachia borealis* (a short-winged mold beetle; Figure 61), 21.±0.99, 26.2-14.4; *Rybaxis clavata* (Figure 62), 28.3±0.41, 29.9-25.1 (Reichle 1967). The moss microhabitats provide them with both the required near-saturation humidities and the multiple temperature ranges they require. Changes in temperature stratification regimes result in different species occurring at different seral stages in the bogs.

![Figure 62. *Rybaxis clavata* adult, a minute beetle that takes advantage of the temperature stratification in a *Sphagnum* bed to meet its temperature needs. Photo by Tom Murray through Creative Commons.](image)

**Scirtidae (=Helodidae) – Marsh Beetles**

This is a worldwide family, but is most diverse in the temperate region (Murray 2005). The larvae live in both stagnant and flowing water where abundant decomposing plant material is present. Adults live on vegetation and on rotting vegetation. The Scirtidae are soft-bodied relative to other beetles and are slightly flattened to nearly subglobular (almost globe-shaped) (TOL 2011). Their sizes range 1-15 mm long. Some females secrete substances that may be pheromones used to stimulate males into courtship (Ruta 2008).

This is typically a beetle of open water, but in a subalpine springbrook in the southern Alps of New Zealand, Scirtidae (Figure 63) are most abundant in the moss *Acrophyllum quadrifarium* (=*Pterygophyllum quadrifarium*; Figure 64) at the edge of the inner spray zone where the mosses are saturated (Cowie & Winterbourn 1979).

![Figure 63. *Helodidae* adult, a beetle that is abundant among *Acrophyllum quadrifarium* in the subalpine springbrooks of the southern Alps of New Zealand. Photo from Pybio at <www.pybio.org>>.](image)
Cyphon (Scirtidae; Figure 65-Figure 67) has been collected from wet mosses at the edge of a cold spring (Usinger 1974). *Cyphon hilaris* (Figure 66) in Dartmoor, UK, prefers bog pools that have *Sphagnum* (Figure 46) (Boyce 2011). In North Hampshire, UK, *C. hilaris* occurs infrequently in wetlands with peaty soils, acidic bogs, and fens (Denton 2013). *Cyphon padi* (Figure 67), also in North Hampshire, prefers peaty areas in wooded sites where the *Sphagnum* is flooded.

Elmidae – Riffle Beetles

These are small beetles (1-8 mm) (Gordon & Post 1965). The *Elmidae* have a distribution similar to that of the *Silphidae*, but there are more known locations, including southern Africa (Harrison 2009). As the common name describes, these beetles usually live in the riffles of cool, rapid streams (Arnett *et al.* 2002; Harpootlian 2005). They feed mostly on decaying plants and algae (Epler 2010).

Only three species of *Elmidae* are considered to be frequent aquatic bryophyte dwellers: *Promoresia tardella* (Figure 68), *Atractelmis wawona* (Figure 69), and *Cleptelmis addenda* (Figure 70) (Brown 1972; Shepard & Barr 1991; Bowles *et al.* 2003; Elliott 2008a), all from North America where the family has many more species (80 species) than in Europe (46 species) (Elliott 2008a). But if one looks among the liverworts in the Pacific states of USA, a fourth genus, *Bryelmis* (Figure 103-Figure 105) is lurking (Bowles *et al.* 2003 – see below); further searching among submerged leafy liverworts may expand this *Bryelmis* distribution. Nevertheless, a number of species use bryophytes at some stage in their lives. Both larvae and adults of some *Elmidae* are able to feed on mosses (Usinger 1974). When disturbed, *Elmidae* may play dead for a number of hours before attempting to relocate (Usinger 1956). *Cleptelmis* (Figure 70) may wait for 12-15 hours before moving. Such patience!
Elmidae colonize mosses when insect-free mosses are introduced, but some of the elmids may be slow to colonize. This is no surprise since they creep and don’t swim. For example, Maurer and Brusven (1983) found that the elmid *Cleptelmis ornata* (Figure 71) was the only insect that was slow to colonize insect-free test clumps of *Fontinalis neomexicana* (Figure 72) during a field experiment in Idaho, USA.

Elliott (2008a) summed up some of the characters that define the bryophyte dwellers. Their larvae have a triangular cross section. Among this group he included *Elmis* (Figure 82-Figure 81), *Esolus* (Figure 79-Figure 80), and *Oulimnius* (Figure 83-Figure 84), none of which were considered by earlier researchers mentioned above to be the frequent bryophyte dwellers. All members of the family have aquatic larvae and most have aquatic adults. The pupae are terrestrial. This means that the newly emerged adults must re-enter the water – no small feat for such a small insect. They must break through the surface tension – easy for us, but nearly impossible for them unless they have something to cling to and provide leverage for them to break through (see Figure 73). Bryophytes, plants, and rocks can help here.

The aquatic adults use the plastron for oxygen availability (Thorpe & Crisp 1949) – they are air breathers. The plastron apparatus is seen as a silvery layer (Figure 74) on the ventral side of the beetle. Some members include...
the antennae as part of the apparatus that holds the air bubble. They groom the plastron with brushes on the femur of the leg and also use these brushes to add air bubbles to the plastron apparatus by smearing bubbles over the plastron. Most do not need to return to the surface, using the mouthparts to capture oxygen bubbles emitted by plants. If the plastron air layer is thick, it has a silvery sheen and is called a macroplastron (Figure 111). When air diminishes from the macroplastron to the normal, smaller plastron, air exchange with the water is generally adequate to maintain the duller-looking air bubble and meet their needs. This low need for fresh air is likely possible because these beetles do not swim, requiring less oxygen for their clambering movements.

In a tributary of the Danube, *Elmis maugetii* and *Riolus subviolaceus* (Figure 75) were abundant in high flow areas among coarse mosses, whereas *Esolus parallelepipedus* (Figure 76) and *Limnius volckmari* (Figure 77-Figure 78) were among algae in moderately flowing water (Dietrich & Waringer 1999). *Esolus angustatus* (Figure 79-Figure 80) and *Oulimnius tuberculatus* (Figure 83-Figure 84) were more common in moderate flow with abundant moss-covered pebbles.

In a 39-month study, Elliott (2008b) examined the effect of density on drift rate. Most of the larvae and adults of *Elmidae* drift at night with very few drifting in daytime. Elliott found that the *Elmidae* in the study, including the bryophyte dwellers, did not drift on the basis of density. Drift losses accounted for only about 0.07% of total losses in the benthos. The exception to this was the high drift, during a heavy rainfall, of early stages of immature adults of *Elmis aenea* (Figure 82), *Oulimnius tuberculatus* (Figure 83-Figure 84), and *Esolus parallelepipedus* (Figure 76), all species known from bryophytes. For *Elmis aenea*, the highest drift density was in the earliest life stage soon after egg hatching; for *O. tuberculatus* it was the start of the larval overwintering period. Frost (1942) found that *Oulimnius tuberculatus* lives among mosses (and other habitats); moving to land for pupation most likely subjects this insect to the drift.

In British streams and rivers, *Elmis aenea* (Figure 81-Figure 82), a moss dweller in rapid streams and rivers (both above and below water), occurred among bryophytes as both adults and larvae, but larvae were more abundant among small stones or under larger ones (Elliott 2008a). In these rivers and streams, *Oulimnius tuberculatus* (Figure 83-Figure 84) preferred tracheophytes.

Nelson (1996) described *Elmis aenea* (Figure 81-Figure 82) as a species from moss-covered rocks in rapid rivers and streams. Berthélémy (1966) found larvae (Figure 81) and adults (Figure 82) of *E. aenea* and *E. maugetii* were often abundant among mosses and liverworts in the Pyrénées. The moss-dwelling species were generally smaller than those among stones. Nelson found that the proportion of *E. aenea* vs *E. riolioides* (Figure 85) among mosses was related to elevation.
Figure 85. *Elmis rioloides* adult, a moss dweller whose distribution is affected by elevation. Photo through Creative Commons.

Gurtz and Wallace (1984) found larvae of the elmid *Promoresia* in only one sample in Big Hurricane Branch. They had learned from J. Haefner (personal communication) that these larvae in Sawmill Branch occurred almost exclusively among aquatic mosses (Haefner & Wallace 1981). I found *Promoresia elegans* (Figure 86-Figure 87) frequently among the bryophytes [*Fontinalis dalecarlica* (Figure 88-Figure 89), *Hygroamblystegium fluviatile* (Figure 90), *Scapania undulata* (Figure 107)] of Appalachian Mountain, USA, streams. This is a genus that exhibits the triangular cross section that Elliott (2008a) suggested to be characteristic of bryophyte dwellers.

In addition to *Elmis*, Berthélémy (1966) found *Riolus cupreus* (Figure 91-Figure 92), *Esolus parallelepipedus* (Figure 76), and *Oulimnius tuberculatus* (Figure 83-Figure 84) among mosses in streams in the Pyrénées. *Elmis* and *Oulimnius* were strong *muscicole* (living among or in association with mosses). Hebauer (1994) found *Elmis obscura*, *E. rioloides* (Figure 85), and *Oulimnius tuberculatus* among mosses in streams in Central Europe.
The *Elmidae* spend their larval life in the water, pupate on land, then after their initial dispersal flight they return to the water. The interesting note here is that once they return to the water, they lose their ability to fly (Ward 1992). This locks them into their habitat no matter what the water conditions. For those inhabiting stream mosses, this means that if the water level drops, they must remain in the habitat of the mosses, unable to disperse for any significant distance. But for them it seems to be no problem because they have a high drought tolerance (Larimore et al. 1959; Iverson et al. 1978).

Steffan (1961) suggested that the mosses such as *Fontinalis* (Figure 89) were necessary for some *Elmidae* and *Dryopidae* to make the transition from water to land (and back to the water) during their amphibious life. Bryophytes would permit them to gain a firm hold while breaking through the surface tension in either direction.

In Louisiana, USA, the endangered riffle beetle *Heterelmis comalensis* (Figure 93-Figure 94) lives on submerged roots and aquatic mosses (Barr & Chapin 1988). In this same habitat, *Microcylloepus pusillus* (Figure 95-Figure 96) likewise uses these substrata. In the Appalachian Mountain streams, USA, I found a species of *Microcylloepus* among the submerged mosses (Glime 1968).
My experience with Elmidae among the stream bryophytes in the Appalachian Mountains, USA, differs from that in many of the reports cited here (Glime 1968). I found six species, and among these only Microcylloepus (Figure 95-Figure 96) and Promoresia elegans (Figure 86-Figure 87) (both larvae and adults) have been reported in the other studies cited herein. The numbers of Promoresia elegans actually exceeded the numbers of Chironomidae among bryophytes in one stream in March; in winter I found only two adults. In addition I found two species of Optioservus (Figure 97-Figure 98) on Hygroamblystegium fluitiale (Figure 90); on Fontinalis dalecarlica (Figure 88-Figure 89), I found Stenelmis crenata (Figure 99-Figure 100) and one species of Dubiraphia (Figure 101-Figure 102).
It is no surprise that new species remain to be discovered among the bryophytes. But one such recent discovery in the western states of the USA was not just a new species, but a new genus, widespread, and with multiple species! And these were among aquatic bryophytes, particularly leafy liverworts (Barr 2011). These three species were *Bryelmis idahoensis* (Figure 103), *B. rivularis* (Figure 104), and *B. siskiyou* (Figure 105) from streams and springs in the states of Washington, Oregon, California, and Idaho. Once Barr alerted her colleagues in neighboring states of her find, they began searching this new habitat, the leafy liverwort *Chiloscyphus polyanthos rivularis* (Figure 106). After searching through 652 adult and over 200 larval specimens from museum and new collections, she distinguished three species, all previously unknown. And now all these people know the difference between a moss and a liverwort – the latter houses *Bryelmis*.

Barr had found *Bryelmis idahoensis* in association with aquatic bryophytes on rocks, but some also occurred on water-soaked wood. *Bryelmis rivularis* preferred *Chiloscyphus polyanthos rivularis* (Figure 106) and *Scapania undulata* (Figure 107) and tended to avoid both of the mosses *Fontinalis neomexicana* (Figure 72) and *Platyhypnidium riparioides* (Figure 108). By targeting aquatic liverworts she discovered another new species, *B. siskiyou*.

In Mexico, Central America, and the West Indies, *Lara avara* (Figure 109-Figure 110) spends 4-6 years as larvae, going through seven instars (Spangler & Santiago-Fragoso 1992). The larvae leave the stream water in spring and move to mosses at the stream bank in their last instar. In their last instar they burrow into small "cells" under mosses at water's edge (Spangler & Santiago-Fragoso 1992) or under mosses on the upper surface of emergent logs (Elliott 2008a). When the moss dries in early summer the larvae begin pupation (Spangler & Santiago-Fragoso 1992). This pupation lasts only two or more weeks.

**Dryopidae – Long-toed Water Beetles**

The *Dryopidae* are mostly Northern Hemisphere (Dryopidae 2015), but the scant records in the Southern Hemisphere may reflect limited collecting rather than absence of beetles. This is an interesting family in that the larvae are mostly terrestrial, living in decaying plant material, rotting wood, and soil, whereas the adults (3.5-5.5 mm long) return to running water to lay eggs (Watson & Dallwitz 2003). They are unable to swim and clamber about by clinging to plants. They eat plants as adults, but larvae may also prey on small animals. The *Dryopidae* occur on every continent except Antarctica and Australia, but they are most common in the tropics (Dryopidae 2015). They use hairs to create a *plastron* apparatus (see introductory information), enabling them to breathe under water.

The *Dryopidae* (Figure 111) seem seldom to be reported among the bryophytes of aquatic habitats. Nevertheless, Percival and Whitehead (1930) found that the *Helminae* (*Dryopidae*) reached 1244 per dm² in the mossy area of streams in the UK, whereas among stones with no mosses they reached only 10-15 per dm². Buczyński et al. (2014) reported that in Poland *Dryops anglicanus* (Figure 112) lives in canals created by beavers in floating *Sphagnum* (Figure 46) mats. In rivers of Northwest Spain, *Dryops luridus* preferred moss substrata (Sarr et al. 2013). In the Appalachian Mountain, USA, streams, I found a species of *Helichus* (Figure 113) (Glime 1968).

Chelonariidae – Turtle Beetles

These are relatively small beetles (adults 2.5-10 mm long) and somewhat resemble turtles in that their heads are hidden and their legs can be tucked into depressions in the abdomen made for them (Harpootlian 2006). They are best known from eastern North America, western South America, and Central America, but there are some records from eastern Asia (Chelonariidae 2015). They reach their greatest diversity in the Neotropics.

Sometimes it is hard to determine if the insects are aquatic or terrestrial. Perhaps it is just a wide niche with a wide water tolerance. In other cases, entrance into the aquatic world may be accidental. Such seems to be the case with *Chelonarium* (Figure 114), a genus that inhabits damp moss (Spangler 1980). From these damp mosses, they may occasionally get washed into the nearby stream by rain or high water (Brown 1972). The larvae, once considered aquatic, lack gills (Spangler 1980). Members of the genus are often associated with the roots of terrestrial epiphytes (plants that grow on other plants but are not parasitic) and often feed on ants and termites.

Lampyridae – Lightning Bugs

"When night closes in, fireflies flicker with an ethereal and haunting light" (WWF 2011). Yes, this is the family of fireflies (Figure 115) that delighted us as children. And one of them lives in the water as a larva (Ho *et al.* 2010). And this species, *Luciola ficta* (see Figure 116), uses mosses! The adults court, mate, and then the females oviposit on mosses (or under leaf litter, in root gaps, or in soil clefts), but on land. The young hatchlings must make their way from their hatching site, including mosses, to the water. Sadly, this unique Asian beetle is in danger of extinction because its habitat is disappearing. However, the Chinese are attempting to save it by learning about its development (Ho *et al.* 2006) and creating special habitats – small pools – for it (WWF 2011).

Figure 116. *Luciola lusitanica* adult. *Luciola ficta* is a species with aquatic larvae and adults that oviposit on terrestrial mosses. Photo by Tim Faasen.
**Latridiidae – Minute Brown Scavenger Beetles**

Minute it is, with sizes up to 3 mm (McClarin 2005). The family mostly eats fungi and slime molds, frequenting decaying vegetation (Latridiidae 2015). Records of this family are concentrated in Europe, with scattered records in North America, South America, Africa, and Australia. But this family is even present in the Antarctic region.

In South Georgia (southern Atlantic Ocean) bryophytes often play an important role as habitats for insects. One such inhabitant is *Aridius malouinensis* (Figure 117) (Arnold & Convey 1998).

![Aridius malouinensis](image1.png)

**Summary**

The suborder polyphaga includes a number of families of beetles that live among bryophytes, especially the small members.

These include Helophoridae that live in both bogs and streams among bryophytes. Hydrochidae live among bog moses. Hydrophilidae are common in bog pools, where diversity is high, but some also occur among stream bryophytes. The Hydraenidae are tiny beetles that live primarily among bryophytes in streams and fast rivers. Some small members of the Ptiliidae are parthenogenetic and live in relict bogs. The Silphidae are carrion feeders and those in bogs breed on small carrion such as frogs. The Staphylinidae are not typical bryophyte dwellers, and are not aquatic, but they live in bogs. The Scirtidae find suitable habitat in the saturated mosses of the spray zone of the springbrooks in the Alps of New Zealand.

The best adapted family of the beetle bryophyte dwellers is the Elmidae. They use a plastron to breathe and are small enough to clamber about among the bryophyte stems and leaves. The Dryopidae are similarly adapted and both families can be found among stream bryophytes.

Some species of the Chelonariidae live among wet moses of stream banks and seem to occasionally fall in. The species *Luciola ficta* is a firefly in the family Lampyridae. Its larvae live in the water and the adults deposit their eggs on mosses and other substrata near water. The Latridiidae are among the insects in South Georgia where one species lives among the bryophytes. The Curculionidae are weevils and few are associated with aquatic habitats. Some live on floating plants and one species leaves its water home to pupate among shoreline moses.

**Curculionidae – Weevils**

Despite the fact that Curculionidae (Figure 118) is the third largest animal family (Curculionidae 2014), its presence is missing among aquatic moses. Its distribution is worldwide, although records are lacking in vast areas of Asia and Africa (Curculionidae 2015). Adults range 1-40 mm long and are plant feeders.

This terrestrial family has limited associations with the water. The marine weevil *Palirhoeus eatoni*, on the Prince Edward Islands south of Africa, lives among tufts of algae as larvae (Doyen 1976). When it pupates it goes above the high water level among clumps of the shoreline moss *Grimmia amblyophylla* (Jeannel 1940, 1953).

**Acknowledgments**

Tim Faasen not only gave me permission to use his wide collection of insect images, he also helped me to understand the ecology of some of the species and provided me with additional images I needed. Thank you to Roger S. Key not only for his permission to use his images but for sharing his experiences with me regarding beetle use of bryophytes. Ronald Willson verified my beetle identifications for the mid-Appalachian Mountain study. Eileen Dumire proofread the chapter and offered suggestions to improve clarity.
